Deep Brain and Cortical Stimulation

Policy Number: 2020T0321W  
Effective Date: January 1, 2020

Coverage Rationale

Deep Brain Stimulation

Deep brain stimulation (excluding directional deep brain stimulation) is proven and medically necessary for treating the following when used according to U.S. Food and Drug Administration (FDA) labeled indications, contraindications, warnings and precautions:

- Essential tremor
- Idiopathic Parkinson's disease
- Primary Dystonia including generalized and/or segmental dystonia, hemidystonia and cervical dystonia (torticollis)

The following are unproven and not medically necessary due to insufficient evidence of efficacy:

- Deep brain stimulation for treating conditions other than those listed above as proven. These include but are not limited to:
  - Chronic pain
  - Cluster headache
  - Depression
  - Epilepsy
  - Impulsive or violent behavior
  - Movement disorders caused by multiple sclerosis (MS)
  - Obsessive-compulsive disorder (OCD)
  - Phantom limb pain
  - Secondary Dystonia
  - Secondary Parkinsonism
  - Stroke pain
  - Tourette syndrome
  - Trigeminal neuralgia

Related Commercial Policy

- Vagus Nerve Stimulation

Community Plan Policy

- Deep Brain and Cortical Stimulation

Medicare Advantage Coverage Summary

- Deep Brain Stimulation for Essential Tremor and Parkinson's Disease
Directional deep brain stimulation that enables specific steering of current towards targeted lesions for treating any condition including but not limited to:

- Dystonia
- Parkinson’s disease
- Tremor

See the Description of Services section for more information regarding directional deep brain stimulation devices.

**Responsive Cortical Stimulation**

Responsive cortical stimulation (e.g., NeuroPace® RNS® System) is proven and medically necessary for treating Partial Onset Seizures when used according to U.S. Food and Drug Administration (FDA) labeled indications, contraindications, warnings and precautions.

Responsive cortical stimulation is unproven and not medically necessary for treating conditions in individuals who do not meet the above criteria due to insufficient evidence of efficacy.

**Documentation Requirements**

Benefit coverage for health services is determined by the member specific benefit plan document and applicable laws that may require coverage for a specific service. The documentation requirements outlined below are used to assess whether the member meets the clinical criteria for coverage but do not guarantee coverage of the service requested.

*For code descriptions, see the Applicable Codes section.

**Definitions**

**Generalized Seizures**: Seizures engaging networks across both cerebral hemispheres (Epilepsy Foundation, 2017).

**Partial Seizures, Partial Onset Seizures, or Focal Onset Seizures**: Seizures originating within networks limited to one cerebral hemisphere (Epilepsy Foundation, 2017).

**Primary Dystonia**: A movement disorder in which dystonia is the only symptom and there is no known acquired cause of the dystonia. Primary Dystonia may occur for unknown reasons or may be inherited (Phukan et al., 2011; American Association of Neurological Surgeons, 2018).

**Secondary Dystonia**: Secondary Dystonia occurs with illness, after trauma or following exposure to certain medications or toxins (Phukan et al., 2011).
Secondary Parkinsonism: Secondary Parkinsonism occurs as a result of head trauma, metabolic conditions, toxicity, drugs, or other medical disorders.

Applicable Codes

The following list(s) of procedure and/or diagnosis codes is provided for reference purposes only and may not be all inclusive. Listing of a code in this policy does not imply that the service described by the code is a covered or non-covered health service. Benefit coverage for health services is determined by the member specific benefit plan document and applicable laws that may require coverage for a specific service. The inclusion of a code does not imply any right to reimbursement or guarantee claim payment. Other Policies and Guidelines may apply.

Description of Services

Deep Brain Stimulation

Deep brain stimulation (DBS) delivers electrical pulses to select areas of the brain (e.g., the internal globus pallidus interna (GPI), subthalamic nucleus (STN) or ventral intermediate nucleus (VIM) of the thalamus) via surgically implanted electrodes. The mechanism of action is not completely understood, but the goal of DBS is to interrupt the pathways responsible for the abnormal movements associated with movement disorders such as Parkinson’s disease and essential tremor. The exact location of electrodes depends on the type of disorder being treated, and unlike standard surgical ablation, which causes permanent destruction of the targeted area, DBS is reversible and adjustable. The DBS device consists of an implantable pulse generator (IPG) or neurostimulator, an implantable lead with electrodes and a connecting wire. The neurostimulator is approximately the size of a stopwatch and is similar to a cardiac pacemaker. Subcutaneous extension wires connect the lead(s) to the neurostimulator which is implanted near the clavicle or, in the case of younger individuals with primary dystonia, in the abdomen. Conventional deep brain stimulation systems deliver stimulation using cylindrical electrodes or Ring Mode (omnidirectional) stimulation, which stimulate neurons around the entire circumference of the lead.

Directional deep brain stimulation uses a directional lead designed to steer electrical current to relevant areas of the brain while avoiding areas that may cause side effects. Several independent electrode contacts can be programmed, creating a more customized therapy. The St. Jude Medical Infinity™ DBS System (Abbott) and the Vercise™ Deep Brain Stimulation System (Boston Scientific) are DBS systems with directional leads.

When used according to U.S. Food and Drug Administration (FDA) indications, deep brain stimulation is used to treat selected individuals with Parkinson's disease, essential tremor, and primary dystonia. Most forms of Parkinson's disease are idiopathic (having no specific known cause). In secondary Parkinsonism, the symptoms are a result of head trauma, metabolic conditions, toxicity, drugs, or other medical disorders. Primary dystonia occurs on its own, apart from any illness. Secondary dystonia can occur with illness, after trauma or following exposure to certain medications or toxins. Types of dystonia include:
- Generalized – Affects multiple areas of the body
- Focal – Affects one specific area of the body, such as the neck (cervical dystonia or torticollis), eyelid (blepharospasm) or hand (writer’s cramp)
- Segmental – Affects two or more adjacent parts of the body
- Multifocal – Affects two nonadjacent parts of the body
- Hemidystonia – Affects one side of the body
- Cervical dystonia or torticollis

Responsive Cortical Stimulation (Closed-Loop Implantable Neurostimulator)

The RNS® System (NeuroPace, Inc.) is intended to detect abnormal electrical brain signals that precede seizures and deliver electrical stimulation in response to try to normalize electrical brain activity and prevent seizures. The device includes a neurostimulator that is placed in the skull and leads that are placed in the seizure-originating areas of the brain. The system’s intended benefits include seizure prevention, fewer adverse events than other neurostimulation methods, and data transmission from the individual’s home to clinicians.

Benefit Considerations

In certain benefit documents (for example, the 2001 Certificate of Coverage), Humanitarian Use Devices (HUDs) require Institutional Review Board (IRB) oversight and are considered to be investigational and not covered. In other benefit documents (for example, the 2007 Certificate of Coverage and subsequent versions), HUDs are not considered to be investigational and are covered when used for proven indications. Please consult the member specific benefit plan document for details.
Clinical Evidence

Deep Brain Stimulation

Parkinson's Disease and Essential Tremor

Evidence from available published studies indicates that deep brain stimulation (DBS) provides clinically and statistically significant improvements in patients with Parkinson's disease (PD) and essential tremor (ET).

In a meta-analysis, Peng et al. (2018) assessed the long-term efficacy of DBS of the subthalamic nucleus (STN) and globus pallidus interna (GPI) for Parkinson disease (PD). Controlled clinical trials were included if they compared STN-DBS versus GPI-DBS in treating idiopathic PD. A total of 5 studies with 890 subjects (437 patients in the STN-DBS group and 453 patients in the GPI-DBS group) were included in the analysis. The study results showed no significant differences between STN-DBS and GPI-DBS in the long-term efficacy of unified Parkinson disease rating scale section (UPDRS) III scores including motor subtypes. The authors concluded that STN-DBS and GPI-DBS improve motor function and activities of daily living for PD.

Roper et al. (2016) conducted a systematic review and meta-analysis on gait speed in patients with PD to summarize the effectiveness of DBS. A random effects model meta-analysis on 27 studies revealed a significant overall standardized mean difference medium effect size equal to 0.60. Based on the synthesis of the 27 studies, the authors determined the following: (1) a significant and medium effect size indicating DBS improves gait speed; (2) DBS improved gait speed regardless of whether the patients were tested in the on or off medication state; and (3) both bilateral and unilateral DBS led to gait speed improvement. According to the authors, the current analysis provides objective evidence that both unilateral and bilateral DBS provide a therapeutic benefit on gait speed in persons with PD.

Tan et al. (2016) conducted a systematic review and meta-analysis to compare DBS stimulation of globus pallidus internus (GPI) and subthalamic nucleus (STN) which are the most targeted locations for the procedure. Clinical outcomes of motor function, non-motor function, and quality of life (QOL) were collected for the meta-analysis. Ten eligible trials with 1,034 patients were included in the analysis. Unified Parkinson's disease rating scale III (UPDRS-III) scores were collected at 6, 12, and 24 months postsurgery separately to assess the motor function of the patients. A statistically significant effect in favor of the GPI DBS was obtained in the off-medication/on-stimulation phase of UPDRS-III at 12 months. However, GPI DBS showed an opposite result at 24 months. In the on-medication/on-stimulation phase, GPI DBS obtained a worse outcome compared with STN DBS. Compared with STN DBS, increased dosage of levodopa equivalent doses was needed in GPI DBS. Meanwhile, Beck Depression Inventory II scores demonstrated that STN has a better performance. As for neurocognitive phase postsurgery, GPI DBS showed better performance in three of the nine tests, especially in verbal fluency. Use of GPI DBS was associated with a greater effect in eight of the nine subscales of QOL. The authors concluded that GPI and STN DBS significantly improve advanced Parkinson's patients' symptoms, functionality, and QOL. According to the authors, the question regarding which target is superior remains open for discussion. An understanding of the target selection depends on individual symptoms, neurocognitive/mood status, therapeutic goals of DBS (e.g., levodopa reduction), and surgical expertise.

In a meta-analysis of randomized controlled trials (RCTs), Perestelo-Perez et al. (2014) described the efficacy of DBS in improving motor signs, functionality and quality of life of PD patients. Six RCTs (n=1,184) that compared DBS plus medication versus medication alone were included in the analysis. The results showed that DBS significantly improves patients' symptoms, functionality and quality of life. Effects sizes are intense for the reduction of motor signs and improvement of functionality in the off-medication phase, in addition to the reduction of the required medication dose and its associated complications. Moderate effects were observed in the case of motor signs and time in good functionality in the on-medication phase, in addition to the quality of life. Although the number of RCTs obtained is small, the total sample size is relatively large, confirming the efficacy of DBS in the control of motor signs and improvement of patients' functionality and quality of life.

To assess the current state of knowledge on essential tremor (ET) therapy and make recommendations based on the analysis of evidence, Zappia et al. (2013) reviewed the literature regarding pharmacologic and surgical therapies, providing a quality assessment of the studies and the strength of recommendations for each treatment. A systematic literature review was performed to identify all the studies conducted on patients with ET. Based on the results of the review, thalamic deep-brain stimulation was recommended for refractory ET.
In a National Institute for Health and Care Excellence (NICE) Guidance for Parkinson’s disease in adults, NICE states that deep brain stimulation should be considered for individuals with advanced Parkinson’s disease whose symptoms are not adequately controlled by best medical therapy (NICE 2017).

Professional Societies

**American Academy of Neurology (AAN)**

The AAN issued an update of the 2005 American Academy of Neurology practice parameter on the treatment of essential tremor (ET) in 2011 (Zesiewicz et al.). The following conclusions and recommendations for deep brain stimulation were unchanged from the 2005 practice parameter:

- DBS of the VIM thalamic nucleus may be used to treat medically refractory limb tremor in essential tremor (Level C - possibly effective, ineffective, or harmful for the given condition in the specified population).
- There is insufficient evidence to make recommendations regarding the use of thalamic DBS for head or voice tremor (Level U - data inadequate or conflicting given current knowledge, treatment is unproven).
- DBS has fewer adverse events than thalamotomy (Level B - probably effective, ineffective, or harmful for the given condition in the specified population). However, the decision to use either procedure depends on each patient’s circumstances and risk for intraoperative complications compared to feasibility of stimulator monitoring and adjustments.

The updated 2011 practice parameter indicated that there were no additional trials (published between 2004 and April 2010) rated better than Class IV that examined the efficacy and safety of DBS of the thalamus for the treatment of ET.

**Dystonia**

**Primary Dystonia**

In a Cochrane systematic review, Rodrigues et al. (2019) compared the efficacy, safety, and tolerability of DBS versus placebo, sham intervention, or best medical care, including botulinum toxin and resective or lesional surgery, in adults with dystonia. The study selection criteria were double-blind, parallel, randomized, controlled trials (RCTs) comparing DBS with sham stimulation, best medical care, or placebo in adults with dystonia. Two RCTs were included in the review, enrolling a total of 102 participants. Both trials evaluated the effect of DBS on the globus pallidus interna and assessed outcomes after three and six months of stimulation. One of the studies included participants with generalized and segmental dystonia; the other included participants with focal (cervical) dystonia. The authors concluded that DBS of the globus pallidus interna may reduce symptom severity and improve functional capacity in adults with cervical, segmental or generalized moderate to severe dystonia, and may improve quality of life in adults with generalized or segmental dystonia.

Moro et al. (2017) conducted a systematic review and meta-analysis to evaluate the clinical evidence of the efficacy of DBS of the globus pallidus internus (GPI) in isolated inherited or idiopathic dystonia. In total, 24 studies were included in the meta-analysis, comprising 523 patients. The mean absolute and percentage improvements in Burke-Fahn-Marsden Dystonia Rating Scale (BFMDRS) motor score at the last follow-up (mean 32.5 months; 24 studies) were 26.6 points and 65.2%, respectively. The corresponding changes in disability score at the last follow-up (mean 32.9 months; 14 studies) were 6.4 points and 58.6%. Multivariate meta-regression of absolute scores indicated that higher BFMDRS motor and disability scores before surgery, together with younger age at time of surgery, were the main factors associated with significantly better DBS outcomes at the latest follow-up. Reporting of safety data was frequently inconsistent and could not be included in the meta-analysis. The authors concluded that patients with isolated inherited or idiopathic dystonia significantly improved after GPI-DBS. Better outcomes were associated with greater dystonia severity at baseline. According to the authors, these findings should be taken into consideration for improving patient selection for DBS.

The National Institute for Health and Care Excellence (NICE) issued a guidance stating that the current evidence supports the safety and efficacy of DBS as a treatment modality for dystonia. This guidance did not however differentiate between primary and secondary dystonia. Dystonia may be treated conservatively or surgically. Conservative treatment only treats the symptoms, and surgical intervention (i.e., thalamotomy and pallidotomy) may not render long-term benefits. Patient selection and management should be managed by a multidisciplinary team specializing in the long-term care of patients with movement disorders (NICE, 2006).

The National Institute for Health and Care Excellence (NICE) issued a guidance stating that the current evidence supports the safety and efficacy of DBS as a treatment modality for dystonia. This guidance did not however differentiate between primary...
and secondary dystonia. Dystonia may be treated conservatively or surgically. Conservative treatment only treats the symptoms, and surgical intervention (i.e., thalamotomy and pallidotomy) may not render long-term benefits. Patient selection and management should be managed by a multidisciplinary team specializing in the long-term care of patients with movement disorders (NICE, 2006).

Secondary Dystonia

There is inadequate evidence of the safety and efficacy of deep brain stimulation for treating secondary dystonia. Questions remain with regard to selection criteria and long-term benefits and safety compared with standard treatments. Formal comparisons, with large randomized controlled or comparative trials of pallidotomy, thalamotomy, and deep brain stimulation, are required before conclusions can be drawn regarding the use of deep brain stimulation for individuals with secondary dystonia.

In a systematic review, Macerollo and Deuschl (2018) analyzed the currently available literature reporting cases with either tardive dystonia (a form of secondary dystonia) or tardive dyskinesia treated with DBS. Thirty-four level VI studies and one level II study with 117 patients were included. Level I studies were not identified. Only four of the patients had tardive dyskinesia. All the others had tardive dystonia. The majority had globus pallidus internum (Gpi-DBS) (n = 109). Patients had a mean age of 47.4 (± SD 14.7) years. The duration of follow-up was 25.6 months ± 26.2. The Abnormal Involuntary Movement Scale was reported in 51 patients with an improvement of 62 ± 15% and the Burke-Fahn-Marsden scale was reported in 67 cases with an improvement of 76 ± 21%. Reported adverse events were surgery-related in 7 patients, stimulation-induced in 12, and psychiatric in 3 patients. These reports suggest favorable effects of DBS and it seems to be relatively safe. The authors indicated that DBS is still a last resort for tardive syndrome (TS) and stimulation parameters and implanted targets are empirical, based on the benefit observed in other more widely explored diseases such as essential tremor and dyskinesia in PD. According to the authors, the limited available data and the lack of a prospective controlled trial prevent them from making final conclusions and recommendations.

Andrews et al. (2010) analyzed combined published results of individual patient outcomes following DBS for all types of dystonia. Data was available in 157 studies for 466 patients with all forms of dystonia. The subclassification of these patients included 344 with primary forms of dystonia, 10 with myoclonus dystonia, 19 with heredodegenerative dystonias and 93 who had DBS for secondary dystonia. Patients with primary forms of dystonia, myoclonus dystonia, subtypes of heredodegenerative dystonia and tardive dystonia have a greater than 50% mean improvement in dystonia severity following DBS. Among patients with primary generalized dystonia, multiple regression analysis showed that a shorter duration of symptoms, a lower baseline severity score and DYT1 positive status were all independently associated with a significantly higher percentage improvement from surgery. Patients with other forms of heredodegenerative and secondary dystonia have variable responses, making prediction of response in future patients difficult.

Koy et al. (2013) performed a meta-analysis and analyzed the published literature regarding DBS and secondary dystonia to evaluate the effect on cerebral palsy, a common cause of secondary dystonia. Twenty articles that included 68 patients with cerebral palsy undergoing deep brain stimulation assessed by the Burke-Fahn-Marsden Dystonia Rating Scale were identified. Most articles were case reports reflecting great variability in the score and duration of follow-up. The mean Burke-Fahn-Marsden Dystonia Rating Scale movement score was 64.94 ± 25.40 preoperatively and dropped to 50.5 ± 26.77 postoperatively, with a mean improvement of 23.6% at a median follow-up of 12 months. There was a significant negative correlation between severity of dystonia and clinical outcome. The authors concluded that deep brain stimulation can be an effective treatment option for dyskinetic cerebral palsy. The authors stated that in view of the heterogeneous data, a prospective study with a large cohort of patients in a standardized setting with a multidisciplinary approach would be helpful in further evaluating the role of deep brain stimulation in cerebral palsy.

Tourette Syndrome

Due to limited studies, small sample sizes, weak study designs, heterogenous study population characteristics, conflicting findings, and the potential for severe adverse events, there is insufficient data to conclude that deep brain stimulation is safe and/or effective for treating Tourette syndrome. Controlled trials are needed to determine the optimal brain target for DBS in individuals with Tourette syndrome.

Pringsheim et al. (2019) systematically evaluated the efficacy of treatments for tics and the risks associated with their use in individuals with Tourette syndrome and chronic tic disorders. Systematic reviews and randomized controlled trials on the
treatment of tics were selected for inclusion in the review if they included at least 20 participants (10 participants if a crossover trial), except for neurostimulation trials, for which no minimum sample size was required. Based on their review, the authors concluded that there is moderate confidence that individuals with tics receiving active DBS of the globus pallidus are probably more likely than those receiving sham DBS of the globus pallidus to have reduced tic severity (2 Class II studies: Kefalopoulou et al., 2015; Welter et al., 2017).

Coulombe et al. (2018) conducted a systematic review to investigate the safety and efficacy of DBS as a treatment for Gilles de la Tourette syndrome (GTS) in children and youth. Twenty-one articles were included in the review. The authors’ results showed an average improvement of 57.5% ± 24.6% across studies on the Yale Global Tic Severity Scale (YGTSS). They also found that comorbid depression and stimulation pulse width each correlated negatively with outcome. In patients with less severe GTS, greater improvements were evident following thalamic stimulation. More than one-quarter (n = 16, 27.6%) of participants experienced side effects, the majority of which were minor. The authors concluded that DBS in the pediatric population may be an effective option with a moderate safety profile for treatment of GTS in carefully selected children and youth. According to the authors, large, prospective studies with long-term follow-up are necessary to understand how DBS influences tic symptoms and may alter the natural course of GTS in children.

Johnson et al. (2019) collected retrospective clinical data and imaging from 13 international sites on 123 patients. The effects of DBS were assessed over time in 110 patients who were implanted in the centromedial (CM) thalamus (n=51), globus pallidus interna (GPI) (n=47), nucleus accumbens/anterior limb of the internal capsule (n=4) or a combination of targets (n=8). Contact locations (n=70 patients) and volumes of tissue activated (n=63 patients) were coregistered to create probabilistic stimulation atlases. Tics and obsessive-compulsive behavior (OCB) significantly improved over time and there were no significant differences across brain targets. The median time was 13 months to reach a 40% improvement in tics, and there were no significant differences across targets, presence of OCB or age at implantation. Active contacts were generally clustered near the target nuclei, with some variability that may reflect differences in targeting protocols, lead models and contact configurations. There were regions within and surrounding GPI and CM thalamus that improved tics for some patients but were ineffective for others. Regions within, superior or medial to GPI were associated with a greater improvement in OCB than regions inferior to GPI. The authors concluded that DBS may be an effective therapy for select cases of treatment-refractory TS, but targeting based on structural anatomy alone may not be sufficient to achieve therapeutic benefit in every patient. According to the authors, future directions for TS DBS should be towards increasing predictive power to be able to integrate symptom profiles, neuroanatomy, functional connectivity, fibre pathway and pathological neural activity in an effort to choose targets and stimulation paradigms that most effectively reduce tics and comorbidities on a patient specific basis.

Servello et al. (2016) performed a systematic review of the published studies on DBS for Tourette's syndrome (TS). The majority of studies were case reports or small series. The thalamus and the globus pallidus internus appear to be the most promising targets. However, in light of the great methodological diversity, a balanced comparison of clinical outcome and understanding of the role of DBS in TS remains problematic. The authors concluded that despite 16 years of experience with DBS in TS a consensus on many issues, foremost on target selection and the age of inclusion continue to be missing. According to the authors, class I evidence with larger patient populations, are urgently needed in order to evaluate the role of DBS in TS.

Baldermann et al. (2016) conducted a systematic literature review to evaluate the efficacy of DBS for severe cases of Tourette syndrome that failed to respond to standard therapies. In total, 57 studies were eligible, including 156 cases. Overall, DBS resulted in a significant improvement of 52.68% in the Yale Global Tic Severity Scale (YGTSS). Analysis of controlled studies significantly favored stimulation versus off stimulation with a standardized mean difference of 0.96. Disentangling different target points revealed significant YGTSS reductions after stimulation of the thalamus, the posterovertralateral part and the anteromedial part of the globus pallidus internus, the anterior limb of the internal capsule and nucleus accumbens with no significant difference between these targets. A significant negative correlation of preoperative tic scores with the outcome of thalamic stimulation was found. Despite small patient numbers, the authors conclude that DBS for GTS is a valid option for medically intractable patients. Different brain targets resulted in comparable improvement rates, indicating a modulation of a common network. According to the authors, the results of this pooled meta-analysis are encouraging but it should be noted that these results are mainly based on studies that must be classified as evidence level IV, according to the classification of the American Academy of Neurology. The authors stated that the efficacy and the individual side effect profile of DBS must be further tested by double blinded, randomized controlled trials with larger sample sizes.

In a randomized, double-blind, controlled trial, Welter et al. (2017) assessed the efficacy of anterior internal globus pallidus (aGPI) DBS for severe Tourette's syndrome. The study included patients aged 18-60 years with severe and medically refractory...
Tourette's syndrome from eight hospitals specialized in movement disorders. Enrolled patients received surgery to implant bilateral electrodes for aGPi DBS; 3 months later they were randomly assigned (1:1 ratio with a block size of eight; computer-generated pairwise randomization according to order of enrolment) to receive either active or sham stimulation for the subsequent 3 months in a double-blind fashion. All patients then received open-label active stimulation for the subsequent 6 months. Patients and clinicians assessing outcomes were masked to treatment allocation; an unmasked clinician was responsible for stimulation parameter programming, with intensity set below the side-effect threshold. Nineteen patients were enrolled in the trial. The investigators randomly assigned 17 (89%) patients, with 16 completing blinded assessments (seven [44%] in the active stimulation group and nine [56%] in the sham stimulation group). There was no clinically or statistically significant difference in YGTSS score change between the beginning and the end of the 3-month double-blind period between groups. During the following 6 month open-label period, stimulation decreased motor and vocal tic severity, with evidence of an improvement in occupational activities and life satisfaction. Fifteen serious adverse events were reported in 13 patients, of which eight events were related to the surgical procedure or hardware. According to the authors, future research is needed to investigate the efficacy of aGPi DBS for patients over longer periods with optimal stimulation parameters and to identify potential predictors of the therapeutic response.

In a randomized, double-blind, crossover trial, Kefalopoulou et al. (2015) recruited eligible patients (severe medically refractory Tourette's syndrome, age ≥20 years) from two clinics for tertiary movement disorders. Enrolled patients received surgery for globus pallidus internus (GPI) DBS and then were randomly assigned in a 1:1 ratio (computer-generated pairwise randomization according to order of enrollment) to receive either stimulation on-first or stimulation off-first for 3 months, followed by a switch to the opposite condition for a further 3 month period. Patients and rating clinicians were masked to treatment allocation; an unmasked clinician was responsible for programming the stimulation. Fifteen patients were enrolled in the study. Fourteen patients were randomly assigned and 13 completed assessments in both blinded periods (seven in the on-first group, six in the off-first group). Mean Yale Global Tic Severity Scale (YGTS) total score in these 13 patients was 87.9 at baseline, 80.7 for the off-stimulation period, and 68.3 for the on-stimulation period. All 15 patients received stimulation in the open-label phase. Overall, three serious adverse events occurred (two infections in DBS hardware at 2 and 7 weeks postoperatively, and one episode of deep-brain-stimulation-induced hypomania during the blinded on-stimulation period); all three resolved with treatment. The authors concluded that GPI stimulation led to a significant improvement in tic severity, with an overall acceptable safety profile. According to the authors, future research should concentrate on identifying the most effective target for DBS to control both tics and associated comorbidities, and further clarify factors that predict individual patient response.

Martinez-Ramirez et al. (2018) assessed the efficacy and safety of DBS in a multinational cohort of patients with Tourette syndrome using the International Deep Brain Stimulation Database and Registry. The registry included 185 patients with medically refractory Tourette syndrome who underwent DBS implantation from January 1, 2012, to December 31, 2016, at 31 institutions in 10 countries worldwide. These patients received DBS implantation in different regions of the brain depending on their symptoms. The mean (SD) total Yale Global Tic Severity Scale score improved from 75.01 (18.36) at baseline to 41.19 (20.00) at 1 year after DBS implantation. The mean (SD) motor tic subscore improved from 21.00 (3.72) at baseline to 12.91 (5.78) after 1 year, and the mean (SD) phonic tic subscore improved from 16.82 (6.56) at baseline to 9.63 (6.99) at 1 year. The overall adverse event rate was 35.4% (56 of 158 patients). The most common stimulation-induced adverse effects were dysarthria (10 [6.3%]) and paresthesia (13 [8.2%]). The authors concluded that deep brain stimulation was associated with symptomatic improvement in patients with Tourette syndrome but also with important adverse events. Long-term assessments will be necessary to monitor adverse effects and determine if DBS has lasting effects on symptoms.

A European guideline on DBS was developed by a working group of the European Society for the Study of Tourette Syndrome (ESSTS). A systematic literature search was conducted, and expert opinions of the guidelines group contributed also to the recommendations. Of 63 patients reported so far in the literature, 59 had a beneficial outcome following DBS with moderate to marked tic improvement. However, randomized controlled studies including a larger number of patients are still lacking. Although persistent serious adverse effects (AEs) have hardly been reported, surgery-related (e.g., bleeding, infection) as well as stimulation-related AEs (e.g., sedation, anxiety, altered mood, changes in sexual function) may occur. According to the ESSTS working group, at the present time, DBS in TS is still in its infancy. Due to both different legality and practical facilities in different European countries these guidelines, therefore, need to be understood as recommendations of experts. However, among the ESSTS working group on DBS in TS there is general agreement that, at present time, DBS should only be used in adult, treatment resistant, and severely affected patients. It is highly recommended to perform DBS in the context of controlled trials (Müller-Vahl et al., 2011).
The First World Congress on Tourette syndrome and tic disorders was held in June of 2016 in London by the Tourette Association of America, Tourette's Action (UK), and the European Society for the Study of Tourette Syndrome. Topics included the use of depth and cortical surface electrodes to investigate the neurophysiology of tics on the background of the evolving field of DBS. The authors indicated that in addition to the conventional treatments of pharmacotherapy and behavioral therapy, alternative approaches are also evolving, ranging from neurosurgical stereotactic DBS, which has a limited evidence base (Mathews and Stern, 2016).

Professional Societies

American Academy of Neurology (AAN)

The AAN published a practice guideline in 2019 on the treatment of tics in people with Tourette syndrome and chronic tic disorders which includes the following recommendations regarding DBS (Pringsheim et al., 2019):

- Physicians must use a multidisciplinary evaluation (psychiatrist or neurologist, neurosurgeon, and neuropsychologist) to establish when the benefits of treatment outweigh the risk for using DBS for medication-resistant motor and phonic tics (Level A - strong recommendation).
- Physicians should confirm the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) diagnosis of TS and exclude secondary and functional tic-like movements when considering DBS for medication-resistant tics (Level B - moderate recommendation).
- A mental health professional must screen patients preoperatively and follow patients postoperatively for psychiatric disorders that may impede the long-term success of the therapy (Level A - strong recommendation).
- Physicians must confirm that multiple classes of medication (antipsychotics, dopamine depleters, alpha-2 agonists) and behavioral therapy have been administered (or contraindicated) before recommending DBS for tics (Level A - strong recommendation).
- Physicians may consider DBS for severe, self-injurious tics, such as severe cervical tics that result in spinal injury (Level C - weak recommendation).

In the rationale section of this practice guideline, the AAN states the following:

- Patients with severe TS, resistant to medical and behavioral therapy, may benefit from DBS
- An important challenge and limitation in the evaluation of the evidence around DBS in TS is that, even in expert DBS centers, few operations per year are performed.
- There is limited information from randomized clinical trials for analysis and interpretation of DBS for treating TS.
- There is no consensus on the optimal brain target for the treatment of tics. The largest available randomized trials for DBS have revealed benefits on motor and phonic tics for the ventral globus pallidus interna and the centromedian thalamic region target; however, these studies have raised methodologic concerns that need to be addressed in future trials.
- Complications of treatment, including infection and removal of hardware, appear more common with TS than with other neurologic conditions.
- There is little information on the effects of DBS on psychiatric comorbidities and the efficacy of DBS in children with TS

International Parkinson and Movement Disorder Society

Recommendations from the International Parkinson and Movement Disorder Society include the following (Schrock et al., 2015):

- DBS used to treat TS, though still evolving, is a promising approach for a subset of medication refractory and severely affected patients
- DBS should be offered to patients only by experienced DBS centers after evaluation by a multidisciplinary team.
- Successes and failures have been reported for multiple brain targets; however, the optimal surgical approach remains unknown.

Depression

Due to limited studies, small sample sizes, weak study designs, heterogenous study population characteristics, conflicting findings, and the potential for severe adverse events, there is insufficient data to conclude that deep brain stimulation is safe and/or effective for treating depression.

Kisely et al. (2018) performed a systematic review and meta-analysis on the effectiveness of DBS in depression. Cochrane Central Register of Controlled Trials, PubMed/Medline, Embase and PsycINFO, Chinese Biomedical Literature Service System,
and China Knowledge Resource Integrated Database were searched for single- or double placebo-controlled, crossover, and parallel-group trials in which DBS was compared with sham treatment using validated scales. Ten papers from nine studies met inclusion criteria, all but two of which were double-blinded RCTs. The main outcome was a reduction in depressive symptoms. It was possible to combine data for 190 participants. Patients on active, as opposed to sham, treatment had a significantly higher response and reductions in mean depression score. However, the effect was attenuated on some of the subgroup and sensitivity analyses, and there were no differences for most other outcomes. In addition, 84 participants experienced a total of 131 serious adverse effects, although not all could be directly associated with the device or surgery. Finally, publication bias was possible. The authors concluded that DBS may show promise for treatment-resistant depression but remains an experimental treatment until further data are available.

McGirr and Berlim (2018) conducted a meta-review of meta-analyses published in the past decade on therapeutic neuromodulation (i.e., repetitive transcranial magnetic stimulation, transcranial direct current stimulation, vagus nerve stimulation and deep brain stimulation) for major depression. According to the authors, vagus nerve stimulation and deep brain stimulation (although more challenging to investigate) have demonstrated preliminary effectiveness, particularly during longer-term follow-up.

In a systematic review, Naesström et al. (2016) reviewed the current studies on psychiatric indications for DBS, with focus on obsessive-compulsive disorder (OCD) and major depressive disorder (MDD). A total of 52 studies met the inclusion criteria with a total of 286 unique patients treated with DBS for psychiatric indications; 18 studies described 112 patients treated with DBS for OCD in six different anatomical targets, while nine studies included 100 patients with DBS for MDD in five different targets. The authors concluded that DBS may show promise for treatment-resistant OCD and MDD but the results are limited by small sample size and insufficient randomized controlled data. According to the authors, other psychiatric indications are currently of a purely experimental nature.

Berlim et al. (2014) conducted a systematic review and exploratory meta-analysis to investigate DBS applied to the subgenual cingulate cortex (SCC) as a potential treatment for severe and chronic treatment-resistant depression (TRD). Data from 4 observational studies were included in the analysis, totaling 66 subjects with severe and chronic TRD. Twelve-month response and remission rates following DBS treatment were 39.9% and 26.3%, respectively. Also, depression scores at 12 months post-DBS were significantly reduced. There was a significant decrease in depression scores between 3 and 6 months, but no significant changes from months 6 to 12. Finally, dropout rates at 12 months were 10.8%. The authors concluded that DBS applied to the SCC seems to be associated with relatively large response and remission rates in the short- and medium- to long-term in patients with severe TRD. Also, its maximal antidepressant effects are mostly observed within the first 6 months after device implantation. According to the authors, these findings are clearly preliminary and future controlled trials should include larger and more representative samples and focus on the identification of optimal neuroanatomical sites and stimulation parameters.

A Comparative Effectiveness Review was prepared for the Agency for Healthcare Research and Quality (AHRQ) on Nonpharmacologic Interventions for Treatment-Resistant Depression in Adults. The report indicated that clinical trial data on some of the developing nonpharmacologic interventions, such as deep brain stimulation were insufficient (from the published literature) to include them in the report. The authors stated that as the evidence bases grow to support the efficacy of such nonpharmacologic interventions, the newer strategies should be included in comparative effectiveness study designs (Gaynes et al., 2011).

**Professional Societies**

**American Psychiatric Association (APA)**

In a clinical practice guideline for the treatment of patients with major depressive disorder, the APA states that electroconvulsive therapy remains the treatment of best established efficacy against which other stimulation treatments (e.g., VNS, deep brain stimulation, transcranial magnetic stimulation, other electromagnetic stimulation therapies) should be compared. The APA did not assign a rating for the use deep brain stimulation in treating depression (Gelenberg et al., 2010).

**Epilepsy**

Due to limited studies, small sample sizes, weak study designs, heterogenous study population characteristics, conflicting findings, and the potential for severe adverse events, there is insufficient data to conclude that deep brain stimulation is safe and/or effective for treating epilepsy.
Herrman et al. (2019) studied the safety and effect of anterior thalamic nucleus deep brain stimulation on seizure frequency in a prospective, randomized, double-blinded study. Patients were followed for 12 months. The first 6 months were blinded with regard to active stimulation or not. After 6 months, all patients received active stimulation. Bilateral anterior nucleus of the thalamus (ANT) electrodes were implanted into 18 patients suffering from focal, pharmaco-resistant epilepsy. Antiepileptic treatment was kept unchanged from three months prior to operation. The Liverpool seizure severity scale (LSSS) was used to measure the burden of epilepsy. There was no significant difference between the 2 groups at the end of the blinded period at 6 months. However, when considering all patients and comparing 6 months of stimulation with baseline, there was a significant, 22% reduction in the frequency of all seizures. Four patients had ≥50% reduction in total seizure frequency and 5 patients had ≥50% reduction in focal seizures after 6 months of stimulation. No increased effect over time was shown. LSSS at 6 months compared to baseline showed no significant difference between the 2 groups, but a small, significant reduction in LSSS was found when all patients had received stimulation for 6 months. According to the authors, this study supports results from earlier studies concerning DBS as a safe treatment option, with effects even in patients with severe, refractory epilepsy. This study was stopped following the interim analysis due to lack of benefit and potential worsening in some patients.

In a meta-analysis and systematic review, Chang and Xu (2018) identified possible predictors of remarkable seizure reduction (RSR) for deep brain stimulation (DBS) in patients with refractory temporal lobe epilepsy (TLE). The authors conducted a comprehensive search of English-language literature published since 1990 that addressed seizure outcomes in patients who underwent DBS for refractory TLE. A pooled RSR rate was determined for eight included studies. RSR rates were analyzed relative to potential prognostic variables. Random- or fixed-effects models were used depending on the presence or absence of heterogeneity. The pooled RSR rate among 61 DBS-treated patients with TLE from 8 studies was 59%. Higher likelihood of RSR was found to be associated with lateralization of stimulation, lateralized ictal EEG findings, and a longer follow-up period. Seizure semiology, MRI abnormalities, and patient sex were not predictive of RSR rate. Hippocampal and anterior thalamic nuclei (ATN) sites of stimulation had similar odds of producing RSR. The authors concluded that DBS is an effective therapeutic modality for intractable TLE, particularly in patients with lateralized EEG abnormalities and in patients treated on the ictal side. Studies with higher levels of evidence and larger populations are needed to determine if DBS is effective for treating epilepsy.

Zhou et al. (2018) evaluated the studies published on the topic of open-loop DBS for epilepsy over the past decade (2008 to present). Among the 41 articles included in the analysis, 19 reported on stimulation of the anterior nucleus of the thalamus, 6 evaluated stimulation of the centromedian nucleus of the thalamus, and 9 evaluated stimulation of the hippocampus. The remaining 7 articles reported on the evaluation of alternative DBS targets. The authors evaluated each study for overall epilepsy response rates as well as adverse events and other significant, non-epilepsy outcomes. According to the authors, one level I trial, the SANTE trial, supported the safety and efficacy of stimulating the anterior nucleus of the thalamus and the hippocampus for the treatment of medically refractory epilepsy. Level III and IV evidence supports stimulation of other targets for epilepsy. Ongoing research into the efficacy, adverse effects, and mechanisms of open-loop DBS is required.

Sprengers et al. (2017) assessed the efficacy, safety and tolerability of DBS and cortical stimulation for refractory epilepsy based on randomized controlled trials (RCTs). The RCTs selected for the review compared deep brain or cortical stimulation versus sham stimulation, resective surgery, further treatment with antiepileptic drugs or other neurostimulation treatments (including vagus nerve stimulation). Twelve RCTs were identified, eleven of these compared one to three months of intracranial neurostimulation with sham stimulation. The authors concluded that except for one very small RCT, only short-term RCTs on intracranial neurostimulation for epilepsy are available. Compared to sham stimulation, one to three months of anterior thalamic DBS ((multi)focal epilepsy), responsive ictal onset zone stimulation ((multi)focal epilepsy) and hippocampal DBS (temporal lobe epilepsy) moderately reduce seizure frequency in refractory epilepsy patients. Anterior thalamic DBS is associated with higher rates of self-reported depression and subjective memory impairment. According to the authors, there is insufficient evidence to make firm conclusive statements on the efficacy and safety of hippocampal DBS, centromedian thalamic DBS, nucleus accumbens DBS and cerebellar stimulation. There is a need for more, large and well-designed RCTs to validate and optimize the efficacy and safety of invasive intracranial neurostimulation treatments.

In a National Institute for Health and Care Excellence (NICE) Guidance for deep brain stimulation for refractory epilepsy, NICE stated that the evidence on the efficacy of deep brain stimulation for refractory epilepsy is limited in both quantity and quality. NICE recommends that this procedure should only be used with special arrangements for clinical governance, consent and audit or research (NICE, 2012).
Obsessive Compulsive Disorder (OCD)

Due to limited studies, small sample sizes, weak study designs and heterogenous study population characteristics, there is insufficient data to conclude that deep brain stimulation is safe and/or effective for treating obsessive-compulsive disorder (OCD).

Vázquez-Bourgon et al. (2019) systematically reviewed the literature to identify the main characteristics of DBS, its use and applicability as treatment for OCD. According to the authors, the critical analysis of the evidence showed that the use of DBS in treatment-resistant OCD is providing satisfactory results regarding efficacy, with assumable side-effects. However, there is insufficient evidence to support the use of any single brain target over another. Patient selection has to be done following analyses of risks/benefits, being advisable to individualize the decision of continuing with concomitant psychopharmacological and psychological treatments. The authors concluded that the use of DBS is still considered to be in the field of research, although it is increasingly used in refractory OCD, producing in the majority of studies significant improvements in symptomatology, and in functionality and quality of life. Random and controlled studies need to be done to determine its long-term efficacy.

Rapinesi et al. (2019) conducted a systematic review to assess the effect of brain stimulation techniques in OCD. DBS showed best results when targeting the crossroad between the nucleus accumbens and the ventral capsule or the subthalamic nucleus. The authors concluded that different brain stimulation techniques are promising as an add-on treatment of refractory OCD, although studies frequently reported inconsistent results. DBS could possibly find some use with adequate testing, but its standard methodology still needs to be established. The authors indicated that the review was limited because of the inclusion of methodologically inconsistent underpowered studies.

In a systematic review, Naesström et al. (2016) reviewed the current studies on psychiatric indications for DBS, with focus on OCD and major depressive disorder (MDD). A total of 52 studies met the inclusion criteria with a total of 286 unique patients treated with DBS for psychiatric indications; 18 studies described 112 patients treated with DBS for OCD in six different anatomical targets, while nine studies included 100 patients with DBS for MDD in five different targets. The authors concluded that DBS may show promise for treatment-resistant OCD and MDD but the results are limited by small sample size and insufficient randomized controlled data. According to the authors, other psychiatric indications are currently of a purely experimental nature.

Hamani et al. (2014) conducted a systematic review of the literature and developed evidence-based guidelines on DBS for OCD that was sponsored by the American Society for Stereotactic and Functional Neurosurgery and the Congress of Neurological Surgeons (CNS) and endorsed by the CNS and American Association of Neurological Surgeons. Of 353 articles identified, 7 were retrieved for full-text review and analysis. The quality of the articles was assigned to each study and the strength of recommendation graded according to the guidelines development methodology of the American Association of Neurological Surgeons/Congress of Neurological Surgeons Joint Guidelines Committee. Of the 7 studies, 1 class I and 2 class II double-blind, randomized, controlled trials reported that bilateral DBS is more effective in improving OCD symptoms than sham treatment. The authors concluded that based on the data published in the literature, the following recommendations can be made: (1) There is Level I evidence, based on a single class I study, for the use of bilateral subthalamic nucleus DBS for the treatment of medically refractory OCD. (2) There is Level II evidence, based on a single class II study, for the use of bilateral nucleus accumbens DBS for the treatment of medically refractory OCD. (3) There is insufficient evidence to make a recommendation for the use of unilateral DBS for the treatment of medically refractory OCD. The authors noted that additional research is needed to determine which patients respond to deep brain stimulation and if specific targets may be more suitable to treat a specific set of symptoms.

Professional Societies

American Psychiatric Association (APA)

In a Guideline Watch Practice Guideline for the Treatment of Patients with OCD, the APA states that new studies are available on DBS and other somatic treatments, but the overall strength of evidence for these treatments remains low (APA, 2013).

Other Disorders

DBS has also been investigated for other disorders including Alzheimer’s disease (Bittlinger and Muller, 2018; Smith et al., 2012; Hardenacke et al., 2013), impulsive or violent behavior (Franzini et al., 2005), chronic and poststroke pain (Frizon et al.,
In a prospective, double-blind trial, Dembek et al. (2017) investigated whether directional DBS of the subthalamic nucleus in Parkinson’s disease (PD) offers increased therapeutic windows, side-effect thresholds, and clinical benefit. In 10 patients, 20 monopolar reviews were conducted to identify the best stimulation directions and compare them to conventional circular DBS. In addition, circular and best-directional DBS were directly compared in a short-term crossover. Motor outcome was also assessed after an open-label follow-up of 3 to 6 months. Stimulation in the individual best direction resulted in significantly larger therapeutic windows, higher side-effect thresholds, and more improvement in hand rotation than circular DBS. Rigidity and finger tapping did not respond differentially to the stimulation conditions. There was no difference in motor efficacy or stimulation amplitudes between directional and circular DBS in the short-term crossover. Follow-up evaluations 3 to 6 months after implantation showed improvements in motor outcome and medication reduction comparable to other DBS studies with a majority of patients remaining with a directional setting. The authors concluded that directional DBS can increase side-effect thresholds while achieving clinical benefit comparable to conventional DBS. However, the question of whether directional DBS improves long-term clinical outcome needs to be investigated in the future.

Timmermann et al. (2015) conducted a prospective, multicentre, non-randomized, open-label intervention study of an implantable DBS device (Vercise PC System that uses a steerable axial shaping of the electrical stimulation field) at six specialist DBS centers at universities in six European countries. Patients were included if they were aged 21-75 years and had been diagnosed with bilateral idiopathic Parkinson’s disease with motor symptoms for more than 5 years. Participants underwent bilateral implantation in the subthalamic nucleus of a multiple-source, constant-current, eight-contact, rechargeable DBS system, and were assessed 12, 26, and 52 weeks after implantation. The primary endpoint was the mean change in unified Parkinson’s disease rating scale (UPDRS) III scores (assessed by site investigators who were aware of the treatment assignment) from baseline (medication-off state) to 26 weeks after first lead implantation (stimulation-on, medication-off state). Of 53 patients enrolled in the study, 40 received a bilateral implant in the subthalamic nucleus and their data contributed to the primary endpoint analysis. Improvement was noted in the UPDRS III motor score 6 months after first lead implantation compared with baseline, with a mean difference of 23.8. One patient died of pneumonia 24 weeks after implantation, which was judged to be unrelated to the procedure. 125 adverse events were reported, the most frequent of which were dystonia, speech disorder, and apathy. 18 serious adverse events were recorded, three of which were attributed to the device or procedure (one
Responsive Cortical Stimulation

There is evidence to support the use of responsive cortical stimulation for treating partial onset seizures when used according to FDA labelled indications. However, there is limited evidence to support the use of responsive cortical stimulation for treating other indications or conditions. Additional studies are needed to evaluate the safety and effectiveness of responsive cortical stimulation for other indications.

Morrell et al. (2011) conducted a multicenter, double-blind, randomized controlled trial that assessed the safety and effectiveness of responsive cortical stimulation as an adjunctive therapy for partial onset seizures in adults with medically refractory epilepsy. A total of 191 adults with medically intractable partial epilepsy were implanted with a responsive neurostimulator connected to depth or subdural leads placed at 1 or 2 predetermined seizure foci. The neurostimulator was programmed to detect abnormal electrocorticographic activity. One month after implantation, subjects were randomized 1:1 to receive stimulation in response to detections (treatment) or to receive no stimulation (sham). Efficacy and safety were assessed over a 12-week blinded period and a subsequent 84-week open-label period during which all subjects received responsive stimulation. Seizures were significantly reduced in the treatment compared to the sham group during the blinded period and there was no difference between the treatment and sham groups in adverse events. During the open-label period, the seizure reduction was sustained in the treatment group and seizures were significantly reduced in the sham group when stimulation began. There were significant improvements in overall quality of life and no deterioration in mood or neuropsychological function. According to the authors, responsive cortical stimulation reduces the frequency of disabling partial seizures, is associated with improvements in quality of life, and is well-tolerated with no mood or cognitive effects. This study provides Class I evidence that responsive cortical stimulation is effective in significantly reducing seizure frequency for 12 weeks in adults who have failed 2 or more antiepileptic medication trials, 3 or more seizures per month, and 1 or 2 seizure foci. The RNS system manufacturer NeuroPace sponsored this study and participated in acquisition of data, statistical analysis, study supervision, and approval of the data. Therefore, a conflict of interest may exist.

Heck et al. (2014) published the final two-year results of the responsive neurostimulation (RNS) pivotal randomized multicenter double-blinded controlled trial described above (Morrell, et al., 2011) to assess the safety and effectiveness of responsive stimulation at the seizure focus as an adjunctive therapy to reduce the frequency of seizures in adults with medically intractable partial onset seizures arising from one or two seizure foci. Subjects with medically intractable partial onset seizures from one or two foci were implanted, and 1-month postimplant were randomized 1:1 to active or sham stimulation. After the fifth postimplant month, all subjects received responsive stimulation in an open label period (OLP) to complete 2 years of postimplant follow-up. All 191 subjects were randomized. The percent change in seizures at the end of the blinded period was -37.9% in the active and -17.3% in the sham stimulation group. The median percent reduction in seizures in the OLP was 44% at 1 year and 53% at 2 years, which represents a progressive and significant improvement with time. The serious adverse event rate was not different between subjects receiving active and sham stimulation. Adverse events were consistent with the known risks of an implanted medical device, seizures, and of other epilepsy treatments. There were no adverse effects on neuropsychological function or mood. According to the authors, responsive stimulation to the seizure focus reduced the frequency of partial-onset seizures acutely, showed improving seizure reduction over time, was well tolerated, and was acceptably safe.

Jobst et al. (2017) reported on the patients from the Morrell, et al. (2011) and Heck et al. (2014) randomized controlled trial to evaluate the seizure-reduction response and safety of brain-responsive stimulation in adults with medically intractable partial-onset seizures of neocortical origin. Patients with partial seizures of neocortical origin were identified from prospective clinical trials of a brain-responsive neurostimulator (RNS System, NeuroPace). The seizure reduction over years 2-6 postimplantation was calculated by assessing the seizure frequency compared to a preimplantation baseline. Safety was assessed based on reported adverse events. Additional analyses considered safety and seizure reduction according to lobe and functional area (e.g., eloquent cortex) of seizure onset. There were 126 patients with seizures of neocortical onset. The average follow-up was 6.1 implant years. The median percent seizure reduction was 70% in patients with frontal and parietal seizure onsets, 58% in those with temporal neocortical onsets, and 51% in those with multilobar onsets. Twenty-six percent of patients experienced at least one seizure-free period of 6 months or longer and 14% experienced at least one seizure-free period of 1 year or longer. Stimulation parameters used for treatment did not cause acute or chronic neurologic deficits, even in eloquent cortical areas.
The rates of infection (0.017 per patient implant year) and perioperative hemorrhage (0.8%) were not greater than with other neurostimulation devices. The authors concluded that brain-responsive stimulation represents a safe and effective treatment option for patients with medically intractable epilepsy, including adults with partial-onset seizures of neocortical onset, and those with onsets from eloquent cortex.

Meador et al. (2015) reported on the patients from the Morrell, et al. (2011) and Heck et al. (2014) randomized controlled trial to evaluate quality of life, which was a supportive analysis, and for mood, which was assessed as a secondary safety endpoint. The study was a multicenter randomized controlled double-blinded trial of responsive neurostimulation in 191 patients with medically resistant focal epilepsy. During a 4-month postimplant blinded period, patients were randomized to receive responsive stimulation or sham stimulation, after which all patients received responsive neurostimulation in open label to complete 2 years. Quality of life (QOL) and mood surveys were administered during the baseline period, at the end of the blinded period, and at year 1 and year 2 of the open label period. The treatment and sham groups did not differ at baseline. Compared with baseline, QOL improved in both groups at the end of the blinded period and also at 1 year and 2 years, when all patients were treated. At 2 years, 44% of patients reported meaningful improvements in QOL, and 16% reported declines. There were no overall adverse changes in mood or in suicidality across the study. Findings were not related to changes in seizures and antiepileptic drugs, and patients with mesial temporal seizure onsets and those with neocortical seizure onsets both experienced improvements in QOL. The authors concluded that treatment with targeted responsive neurostimulation does not adversely affect QOL or mood and may be associated with improvements in QOL in patients, including those with seizures of either mesial temporal origin or neocortical origin.

Bergey et al. (2015) reported on patients who were involved in the Morrell et al. (2011) and Heck et al. (2014) studies and transitioned to this open-label study that assessed the long-term efficacy and safety of responsive direct neurostimulation in adults with medically refractory partial onset seizures. All participants were treated with a cranially implanted responsive neurostimulator that delivers stimulation to 1 or 2 seizure foci via chronically implanted electrodes when specific electrocorticographic patterns are detected (RNS System). Participants had completed a 2 year primarily open-label safety study (n = 65) or a 2 year randomized blinded controlled safety and efficacy study (n = 191); 230 participants transitioned into an ongoing 7-year study to assess safety and efficacy. The average participant was 34 (±11.4) years old with epilepsy for 19.6 (±11.4) years. The median preimplant frequency of disabling partial or generalized tonic-clonic seizures was 10.2 seizures a month. The median percent seizure reduction in the randomized blinded controlled trial was 44% at 1 year and 53% at 2 years and ranged from 48% to 66% over postimplant years 3 through 6 in the long-term study. Improvements in quality of life were maintained. The most common serious device-related adverse events over the mean 5.4 years of follow-up were implant site infection (9.0%) involving soft tissue and neurostimulator explantation (4.7%). The authors concluded that acute and sustained efficacy and safety were demonstrated in adults with medically refractory partial onset seizures arising from 1 or 2 foci over a mean follow-up of 5.4 years. This experience supports the RNS System as a treatment option for refractory partial seizures. This study provides Class IV evidence that for adults with medically refractory partial onset seizures, responsive direct cortical stimulation reduces seizures and improves quality of life over a mean follow-up of 5.4 years.

A guideline published by the U.S. Department of Veterans Affairs in 2014, titled Department of Veterans Affairs Epilepsy Manual, mentioned using the RNS System to treat epilepsy. In the Investigational Treatments section, this guideline states that although RNS has positive results (in a randomized trial), the overall effectiveness of this device was only slightly superior to vagus nerve stimulation (VNS) during the blinded phase of this study. The guideline concludes that RNS is currently considered a potential treatment option for patients with two seizure foci, or with a single focus not amenable to resection (Husain et al., 2014).

U.S. Food and Drug Administration (FDA)

This section is to be used for informational purposes only. FDA approval alone is not a basis for coverage.

Deep Brain Stimulation

Deep brain stimulation is a procedure and, therefore, not subject to FDA regulation. However, any medical devices, drugs, and/or tests used as part of this procedure may require FDA regulation.
**Parkinson’s Disease and Essential Tremor**

The FDA approved the Activa® Tremor Control System (Medtronic) on July 31, 1997. The device is indicated for unilateral thalamic stimulation for the suppression of tremor in the upper extremity in patients who are diagnosed with essential tremor or Parkinsonian tremor not adequately controlled by medications and where the tremor constitutes a significant functional disability. In 2015, the FDA labeled indications for Activa Tremor Control System for Parkinson’s disease was modified to include “adjunctive therapy in reducing some of the symptoms in individuals with levodopa-responsive Parkinson’s disease of at least 4 years duration that are not adequately controlled with medication. See the following websites for more information:

(Accessed October 10, 2019)

A January 14, 2002 Premarket Approval (PMA) supplement expanded use of Activa Parkinson’s Control Therapy to include bilateral stimulation of the internal globus pallidus (GPI) or the subthalamic nucleus (STN) as an adjunctive therapy in reducing some of the symptoms of advanced, levodopa-responsive Parkinson’s disease that are not adequately controlled with medication. Available at: [http://www.accessdata.fda.gov/cdrh_docs/pdf/P960009S007b.pdf](http://www.accessdata.fda.gov/cdrh_docs/pdf/P960009S007b.pdf). (Accessed October 10, 2019)

On June 12, 2015, the FDA approved the Brio Neurostimulation System (Abbott), an implantable deep brain stimulation device intended to help reduce the symptoms of Parkinson’s disease and essential tremor. See the following website for more information: [http://www.accessdata.fda.gov/cdrh_docs/pdf14/P140009a.pdf](http://www.accessdata.fda.gov/cdrh_docs/pdf14/P140009a.pdf). (Accessed October 10, 2019)

**Directional Deep Brain Stimulation**

On September 19, 2016, the FDA approved a Premarket Approval (PMA) application bundles supplement (P140009/S001) approving the use of the St. Jude Medical Infinity™ DBS System. The FDA approval for the Infinity DBS System is a supplement to an earlier PMA (P140009) for the St. Jude Medical Brio Neurostimulation system. According to the manufacturer, the Infinity DBS System and the Brio Neurostimulation System have the same indications for use. See the following website for more information: [http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfpma/pma.cfm?id=P140009](http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfpma/pma.cfm?id=P140009). (Accessed September 23, 2019)

**Dystonia**

On April 15, 2003, the Activa® Dystonia Therapy System (Medtronic) received a Humanitarian Device Exemption (HDE) from the FDA for unilateral and bilateral stimulation of the internal globus pallidus or the subthalamic nucleus and is indicated as an aid in the treatment of chronic, intractable (drug refractory), primary dystonia, including generalized and segmental dystonia, hemidystonia and cervical dystonia. Activa Dystonia Therapy is limited to use in implanting centers that receive Institutional Review Board (IRB) approval for the procedure. The safety and effectiveness of Activa Dystonia Therapy have not been established through a full PMA study. The therapy is approved for patients who are seven years of age and older. Available at: [https://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfhde/hde.cfm?id=H020007](https://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfhde/hde.cfm?id=H020007). (Accessed October 10, 2019)

**Other Indications**

On March 28, 2005, the Activa® Deep Brain Stimulation Therapy System was designated as a Humanitarian Use Device (HUD) for the treatment of chronic, treatment-resistant obsessive-compulsive disorder (OCD) in a subset of patients. However, the FDA does not list a Humanitarian Device Exemption (HDE) approval for authorization to market the device.

On February 19, 2009, the Reclaim™ Deep Brain Stimulation Therapy device was designated as a HUD for the treatment of obsessive compulsive disorder (OCD). This device is indicated for bilateral stimulation of the anterior limb of the internal capsule (AIC) as an adjunct to medications and as an alternative to anterior capsulotomy for treatment of chronic, severe, treatment-resistant OCD in adult patients who have failed at least three selective serotonin reuptake inhibitors (SSRIs). See the following website for more information: [https://www.accessdata.fda.gov/cdrh_docs/pdf5/H050003a.pdf](https://www.accessdata.fda.gov/cdrh_docs/pdf5/H050003a.pdf). (Accessed October 10, 2019)
On April 27, 2018, the FDA approved the Medtronic DBS System for Epilepsy for bilateral stimulation of the anterior nucleus of the thalamus (ANT). See the following website for more information: https://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfpma/pma.cfm?id=P960009S219. (Accessed September 23, 2019)

Responsive Cortical Stimulation

The FDA approved the NeuroPace RNS Neurostimulator System on November 14, 2013. The device is indicated as an adjunctive therapy in reducing the frequency of seizures in individuals 18 years of age or older with partial onset seizures who have undergone diagnostic testing that localized no more than two epileptogenic foci, are refractory to two or more antiepileptic medications, and currently have frequent and disabling seizures (motor, partial seizures, complex partial seizures and/or secondarily generalized seizures). The RNS System has demonstrated safety and effectiveness in patients who average three or more disabling seizures per month over the three most recent months (with no month with fewer than two seizures) and has not been evaluated in patients with less frequent seizures.

The RNS System is contraindicated for:

- Patients with risk factors for surgical complications such as active systemic infection, coagulation disorders (such as the use of antithrombotic therapies), or platelet count below 50,000
- Patients who have implanted medical devices that deliver electrical energy to the brain
- Patients who are unable or do not have the necessary assistance to properly operate the NeuroPace remote monitor or magnet

The following medical procedures are contraindicated for patients with an implanted RNS System. The procedures may send energy through the implanted brain stimulation system causing permanent brain damage, which may result in severe injury, coma, or death. Brain damage can occur from any of the listed procedures even if the RNS neurostimulator is turned off, the leads are not connected to the neurostimulator, or the neurostimulator has been removed and any leads (or any part of a lead) remain:

- MRI
- Diathermy procedures (high-frequency electromagnetic radiation, electric currents, or ultrasonic waves used to produce heat in body tissues) (Patients should not be treated with any type of shortwave, microwave, or therapeutic ultrasound diathermy device, on any part of the body, regardless of whether the device is used to produce heat.)
- Electroconvulsive therapy
- Transcranial magnetic stimulation

See the following website for more information: https://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfPMA/pma.cfm?id=P100026. (Accessed October 10, 2019)

Additional Products

- Activa® Tremor Control Therapy (Medtronic, Inc.)
- Activa® Parkinson's Control Therapy (Medtronic, Inc.)
- Activa® Dystonia Therapy (Medtronic, Inc.)
- Kinetra® Neurostimulator (Medtronic, Inc.)
- Soletra® Neurostimulator (Medtronic, Inc.)

Centers for Medicare and Medicaid Services (CMS)

Medicare covers deep brain stimulation (DBS) when criteria are met. Refer to the National Coverage Determination (NCD) for Deep Brain Stimulation for Essential Tremor and Parkinson’s disease (160.24). Local Coverage Determinations (LCDs) do not exist at this time.

Medicare does not have an NCD for responsive cortical stimulation. LCDs do not exist at this time. (Accessed October 18, 2019)

**Instructions for Use**

This Medical Policy provides assistance in interpreting UnitedHealthcare standard benefit plans. When deciding coverage, the member specific benefit plan document must be referenced as the terms of the member specific benefit plan may differ from the standard plan. In the event of a conflict, the member specific benefit plan document governs. Before using this policy, please check the member specific benefit plan document and any applicable federal or state mandates. UnitedHealthcare reserves the right to modify its Policies and Guidelines as necessary. This Medical Policy is provided for informational purposes. It does not constitute medical advice.
This Medical Policy may also be applied to Medicare Advantage plans in certain instances. In the absence of a Medicare National Coverage Determination (NCD), Local Coverage Determination (LCD), or other Medicare coverage guidance, CMS allows a Medicare Advantage Organization (MAO) to create its own coverage determinations, using objective evidence-based rationale relying on authoritative evidence (Medicare IOM Pub. No. 100-16, Ch. 4, §90.5).

UnitedHealthcare may also use tools developed by third parties, such as the MCG™ Care Guidelines, to assist us in administering health benefits. UnitedHealthcare Medical Policies are intended to be used in connection with the independent professional medical judgment of a qualified health care provider and do not constitute the practice of medicine or medical advice.
